Chondroid syringoma of the upper lip: a case report

Üst dudağın kondroid siringoması: Oluğ sunumu

Osman Kürtat ARıKAN, M.D., Sibel ERDOĞAN, M.D., Nuray Bayar MULUK, M.D., Can KOÇ, M.D.

Chondroid syringoma (mixed tumour of the skin) is a rare benign neoplasm of the sweat glands which often occurs in the head and neck region. We present a 73-year-old white farmer man with a mass of anterior surface of the upper lip that was histologically diagnosed as chondroid syringoma after surgical wide excision. There has been no signs of recurrence during a follow-up of 14 months.

Key Words: Adenoma; sweat gland/pathology; lip neoplasms/pathology/surgery.

The chondroid syringoma is a benign mixed tumour of the skin characterized by a mixture of epithelial and mesenchymal tissues.[3] These lesions usually have the appearance of slow-growing, painless swelling, subcutaneous, or intracutaneous nodules in the head and neck region between the ages of 20-70 years, with a distinct male predominance.[2] We report a case of chondroid syringoma which involved the upper lip.

CASE REPORT

The patient, a 73-year-old farmer man, presented with an asymptomatic mass in the anterior surface of the upper lip on February 15, 2002. The lesion had been present for 3 years before admission with slow rate of growth. On physical examination, it was firm, lobulated, measuring 1.5x1x1 cm, painless on palpation, adherent to the surrounding skin but there was no associated skin punctum (Fig. 1). There was no lymphadenopathy in the neck. Under local anaesthesia, the lesion was completely excised, together with a 5-mm margin of normal tissue. The wound was closed primarily and healing was uneventful. There had been no signs of recurrence during a follow-up of 14 months.

The histopathologic examination of the lesion revealed, embedded in chondromyxoid stroma, were epithelial cells arranged in sheets, columns, small nests, large aggregates and double layered tubular structures (Fig. 2).
DISCUSSION

Chondroid syringoma is a benign skin tumour characterized by several histological aspects similar to salivary gland adenomas. They derived from epithelial appendages. It was first suggested as a name for the mixed tumour of skin by Hirsch and Helwig. The tumour develops from eccrine or apocrine glands and seen mainly in the head and neck region between the ages of 20 and 70 years. Of 16,200 skin lesions, Yavuzer et al. found the histopathologic diagnosis of chondroid syringoma in 16 cases (0.098%). After the nose and the skin of the cheek, the upper lip is the most common anatomic location for the development of chondroid syringoma. Its incidence in males is twice as high as in females. The neoplasm is usually an asymptomatic, benign, painless, slow-growing, subcutaneous or intracutaneous nodule that patients want to be removed for aesthetic reasons.

The biologic behavior of chondroid syringoma is benign but a few cases of malignant tumour have been reported. The malignant neoplasm tends to produce metastases to both the regional and distant lymph nodes.

Because chondroid syringomas are rare and have not pathognomonic clinical characteristics, they are often overlooked and the lesion can be confused with a dermoid or sebaceous cyst, compound nevus, basal cell carcinoma, neurofibroma, histiocytoma, pilomatricoma, dermatofibroma and seborrheic keratosis. Fine-needle aspiration cytology has also been described for the diagnosis but such a small lesion remained ineffective. It is therefore clear that the definitive diagnosis can be established only by histopathologic examination.

Histologically, chondroid syringoma correspond to the so-called pleomorphic adenoma of the skin. It is essentially an epithelial lesion characterised by tubuloalveolar and gland-like structures with two or more cuboidal cell lines, islands of cuboidal or polygonal cells in a fibroadipoid, chondroid, hyaline or mucinous stroma. Malignant change in a chondroid syringoma is rare. On microscopic examina-

tion, cytologic atypia, infiltrative margins, increased mitotic figures and tumour necrosis are considered as the signs of malign transformation.\textsuperscript{[8]}

The treatment of choice is local excision. Recurrences are attributed to inadequate surgical excision. If the tumour has been completely excised and is benign, long-term follow-up is not indicated. Our patient has been free of recurrence for 14 months after since the operation.

In the evaluation of an elderly male patient with a firm, slow-growing and painless mass, chondroid syringoma should be included in the differential diagnosis of lesions of the head and neck region.
